## 1 Introduction

### 1.1 What is Optimization in Our Terms

The problem to be address is the minimization of resource usage while maintaining a high level of output. Examples of resources that may be targets for optimization are

**Walltime** — The elapsed time in which the process (or master process) runs.

**CPU Time** — The amount of time that the processor spends doing active computation. This is often very different from the walltime and can be very difficult to control on a time-sharing system. Not typically used.

**FLOPS** — Floating Point operations per second.

**Memory Usage** — Peak use of memory during the computation.

**Number of completed processes within a time period** — For High Throughput computations, it may be better to focus on the number of processes that complete within a certain time period. This can account for some variance due to differences in input sets and that impact on overall performance, but give meaningful expectations in the aggregate.

## 1.2 Example Problem

## 1.3

# 2 Serial Process

## 2.1 Manual Profiling

### 2.1.1 Walltime using the time command

Determining the walltime using `/usr/bin/time` can be a very useful place to start and requires very little intervention.

# 3 Parallel Process

# 4 Conclusion
